

Page 1

A fixed-layout document is drawn, not laid out: the page arrives with its own fonts, its own spacing and its own illustrations already composed, and the reader's job is to put those pixels on the screen unchanged.

That is the whole contract, and it is why this path renders through a canvas instead of extracting text. Anything the reader does to a PDF page has to happen around the bitmap, never to it.

Which makes the cost of a page turn a rendering cost, and rendering is slow enough to see: a page like this one takes tens of milliseconds, and a page dense with vector work takes a good deal more. Whatever the reader is looking at during that time is what they will remember about the turn.

Hence the double buffer. The page already on screen stays there until its replacement exists, and the swap between them happens inside a single task so the browser never paints the gap.

That is the whole contract, and it is why this path renders through a canvas instead of extracting text. Anything the reader does to a PDF page has to happen around the bitmap, never to it.

With this, we can finally write the definition of the $\mathcal{L}_\infty$ norm, which is the $\mathcal{L}_2$ norm of the gradient of the loss function with respect to the weights, averaged over the data points. The $\mathcal{L}_\infty$ norm is defined as follows:

[illegible]
